FLOER COHOMOLOGY OF CERTAIN PSEUDO-ANOSOV MAPS

EAMAN EFTEKHARY

Abstract. Floer cohomology is computed for the elements of the mapping class group of a surface Σ of genus $g > 1$ which are compositions of positive and negative Dehn twists along loops in Σ forming a tree-pattern. The computations cover a certain class of pseudo-Anosov maps.

Dedicated to S. Shahshahani on the occasion of his 60-th birthday

1. INTRODUCTION

The symplectic Floer cohomology (homology) is associated with a compact symplectic $2n$-manifold (M^{2n}, ω), where L_1 and L_2 are two transversal Lagrangian submanifolds of dimension n and ω is the symplectic form. The Floer complex is freely generated by the intersection points of L_1 and L_2. The boundary maps count the pseudo-holomorphic disks between these points with the boundary on the Lagrangian submanifolds (see [3]).

For any symplectic form ω on a surface Σ of genus $g > 1$, there are diffeomorphisms $f : \Sigma \to \Sigma$ in each isotopy class in the mapping class group of Σ, which preserve ω. Putting the symplectic form $\omega \times (-\omega)$ on $\Sigma \times \Sigma$, the diagonal Δ and the graph Γ_f of f will become Lagrangian. One may ask for the symplectic Floer cohomology of this setting, denoted by $HF^*(f)$. There are some technical issues that may arise, in order to make this cohomology group an invariant of the isotopy class. It is shown in [10] that the Floer cohomology of an isotopy class in the mapping class group is a well-defined $\mathbb{Z}/2\mathbb{Z}$ -graded $H^*(\Sigma, \mathbb{Z}/2\mathbb{Z})$ -module. Monotonicity is necessary for using a particular representative of a class in the mapping class group for Floer cohomology computations (see [10]). In [9], this Floer cohomology is computed for a combination of Dehn twists along a disjoint union of curves.

Gautschi extended this result to the case of algebraically finite maps ([4]). These are obtained by choosing disjoint loops α_i on the surface and composing the positive Dehn twists along α_is with finite order automorphisms of $\Sigma \setminus \cup\alpha_i$ which satisfy certain boundary conditions. By Thurston's classification of surface diffeomorphisms these are the maps with no pseudo-Anosov

components.

On the other hand the mapping class group is generated by positive Dehn twists along certain simple closed curves on the surface. This means that each class has a representative given by composition of positive Dehn twists along a collection of curves $\alpha_i, i = 1, 2, ..., n$ on Σ. However, they may have many intersections. Hence it is important to be able to push the computation of Seidel to the case of loops with intersections.

In this paper, the result of [9] is extended in a different direction, by allowing the loops to intersect each other in a “nice” way.

In particular many pseudo-Anosov maps may be obtained by allowing these types of intersections (for instance, see example 4.3). These are the first computations for pseudo-Anosov diffeomorphisms. There are no holomorphic orbits between the generators of the complex if the composition of twists represents a pseudo-Anosov class. It is interesting to study whether in general this is the case .

Definition 1.1. *A set of data $(\Sigma, \alpha_1, \alpha_2, ..., \alpha_n)$ will be called an* acceptable setting *if Σ is a surface of genus $g > 1$ and $\alpha_1, ..., \alpha_n$ are simple closed loops on Σ satisfying the following conditions: Any two of the loops intersect at most once and transversely. If we form the* intersection graph *G with vertices $1, 2, ..., n$, and connect i, j iff α_i, α_j intersect each other, then G is a* forest *(i.e. it does not contain any loops). Furthermore, we assume that no α_i is homologically trivial.*

The map will be the combination of positive Dehn twists along α_is.

The content of section 2 will be the construction of some appropriate Morse function on Σ. Its Hamiltonian flow will be composed with the combination of twists, in order to make the diagonal transversal to the graph of the function in $\Sigma \times \Sigma$. The fixed points of this composition will be in $1-1$ correspondence with the generators of the Floer complex.
In section 3 we will study the moduli spaces of J-holomorphic disks between the fixed points. In particular we will prove some energy bounds. These bounds will be used in section 4 to prove the main result of this paper (theorem 4.1):

Theorem 1.2. *Let $(\Sigma, \alpha_1, ..., \alpha_n)$ be an acceptable setting, $C = \cup_i \alpha_i$ and T be the composition of positive Dehn twists along α_is in some order. Then $HF^*(T) \cong H^*(\Sigma, C)$ as $H^*(\Sigma, \mathbb{Z}/2\mathbb{Z})$-modules where $H^*(\Sigma) \cong HF^*(Id)$*

acts on the right hand side by the cup product and on the left hand side by quantum cup product. (see theorem 4.6 for a more general result).

It is well-known that in the most familiar case, $HF^*(Id) \cong H^*(\Sigma)$ and the quantum cup product reduces to the ordinary cup product (see [5], [6] or [7]).

Acknowledgment. No words can express my thankfulness to Z. Szabó, for his patience in correcting my mistakes, and sharing his insight with me. Some ideas presented here, are suggested by P. Seidel, who kindly taught me a lot on this problem. Many thanks go to M. Hutchings, P. Ozsváth and M. Ajoodanian for the great conversations that we had.

2. Appropriate Morse Functions

We will construct a Morse function inductively, and use its Hamiltonian flow to get a function with the required trasversality. We will implicitly assume that the loops $\alpha_i, i = 1, ..., n$ are smooth.

Proposition 2.1. *Suppose that $\alpha_i, i = 1, 2, ..., n$ are simple closed loops on a surface Σ. Then it is possible to find a Morse function $h : \Sigma \to \mathbb{R}$ such that the curves α_i are unions of the flow line of h and the followings are satisfied:*

(H1) *$h(p) > 4$ for all points $p \in \alpha_i, i = 1, ..., n$.*
(H2) *If p is a critical point of h and $h(p) > 2$ then $p \in \alpha_i$ for some i.*
(H3) *If $\{q\} = \alpha_i \cap \alpha_j$, then q is an index-1 critical point for h*
(H4) *For a critical point $q \in \alpha_i$ of h which is not an intersection point with other α_js, either q is an index-2 critical point, or it has index 1 and $h|_{\alpha_i}$ has a local minimum at q.*

Proof. The proof is by induction on the number of loops. For a union of disjoint loops it is easy to find such a function. Now suppose that a map $h_0 : \Sigma \to \mathbb{R}$ is constructed for $\alpha_1, ..., \alpha_{n-1}$ with the above properties. α_n meets the other curves in some points, say $q_1, ..., q_m$ which we may assume to be different from the critical points of h_0. Suppose that $\{q_i\} = \alpha_n \cap \alpha_{j_i}$ for some $j_i \in \{1, 2, ..., n-1\}$. Change h_0 near each q_i by introducing a pair of cancelling critical points on α_{j_i} of indices $2, 1$ (see figure 1(a)) . Choose them such that q_i is the index-1 critical point and $h|_{\alpha_{j_i}}$ has a local minimum at q_i.

We may assume that near q_i, α_n is the union of the two flow lines going out of this critical point. Let us denote by Φ^T the gradient flow of the new Morse function up to time T. If T is chosen big enough, $\beta = \Phi^T(\alpha_n)$ will be isotopic to α_n, and on $h_0^{-1}[2,\infty)$, β is a union of flow lines. Furthermore, β has no intersection with other α-curves other than q_i. $\Sigma_0 = h_0^{-1}(-\infty, 3]$ is a manifold, which is of the form $(2,3] \times S^1$ near each boundary component. h_0 is the projection onto the second factor on this neighborhood and $\gamma = \beta \cap \Sigma_0$ will be a union of disjoint paths on Σ_0. In this situation the following lemma is fairly easy to prove:

Lemma 2.2. *Suppose that* Σ_0 *is a surface and* $C_1, ..., C_l$ *are the boundary circles with tubular neighborhoods* $N_i = [2,3] \times C_i \subset \Sigma_0$. *Suppose that a union* γ *of disjoint paths* $\gamma_1, ..., \gamma_k$ *with ends on the boundary circles is of the form* $[2,3] \times \{p_1^i, ..., p_{k_i}^i\}$ *in each* N_i. *Then there exists a Morse function* h' *on* Σ_0 *which is the projection onto the first factor on each* N_i, *has value less than* 2 *elsewhere and each* γ_i *is a union of the two flow lines going into an index*-1 *critical points of* h'.

□

Using this lemma we may change h_0 on Σ_0 to be equal to h'. Then α_n is cut into several pieces which are flow lines of the new Morse function h', say $\alpha_n = \gamma_1 \cup ... \cup \gamma_k$. Each γ_j starts from an index-1 critical point p_- and goes down to another index-1 point p_0, then goes back up to a third index-1 critical point p_+ (figure 1(b)). For these points we have $h'(p_+), h'(p_-) > 4$ and $h(p_0) < 2$. By changing h' in the shaded area of figure 1(b) we may

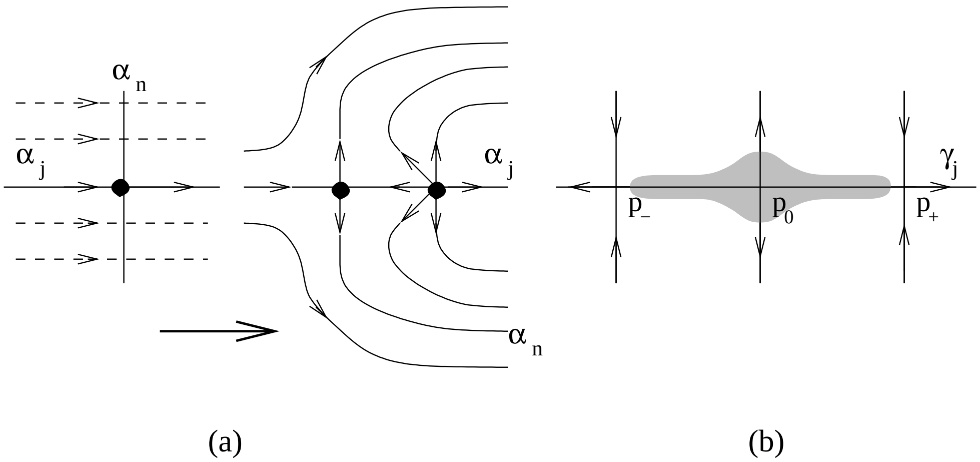

FIGURE 1. (a) Near an intersection point $\alpha_j \cap \alpha_n$ we may introduce an indext-2 critical point on α_j and an index-1 critical point in the intersection, to make α_n locally a flow line. (b) By changing h in the shaded area, we may assume that $h(p_0)$ has any value less that $min\{h(p_-), h(p_+)\}$

move $h'(p_0)$ within the range $min\{h(p_-), h(p_+)\} > h(p_0) > 4$ such that the flow lines between the critical points remain the same. This completes the induction. □

From now on, we will assume that $(\Sigma, \alpha_1, ..., \alpha_n)$ is an acceptable setting and that the positive Dehn twist T_i along α_i is done in small tubular neighborhood of the loop. If we choose the symplectic form to be standard in the neighborhood of α_is, this map may be assumed to be a symplectomorphism.

Now it is time to show how one should use this Morse function h to perturb the combination T of the twists.
Let X_h denote the vector field satisfying:

$$\omega(X_h(x), \zeta) = -dh_x\zeta \quad \forall \;\; \zeta \in T_x\Sigma, \tag{1}$$

where h is the Morse function constructed above. One may consider the flow of this vector field, denoted by $H^t(x)$, which is called the *Hamiltonian flow* of h. Put $T^\epsilon := H^\epsilon \circ T$. The following result determines the fixed points of T^ϵ:

Theorem 2.3. *Suppose that h is the Morse function given by proposition 2.1. Then for $\epsilon > 0$ small enough, the only fixed points of the map T^ϵ constructed above, are the critical points p of h with $h(p) < 2$.*

Proof. First of all notice that if p is a critical point of h, with $h(p) < 2$, then it will be a fixed point of T^ϵ. We claim that these are actually the only fixed points. Away from small strips around the loops, T is the identity map and the above claim is trivial. Now, assume that p is a fixed point in this region. H^ϵ will not change the "height" of the points (i.e. $h(H^\epsilon(x)) = h(x)$) and each point is only moved slightly by H^ϵ. Since p is a fixed point of T^ϵ, T should have the same property. This is not the case away from the critical points of h.

In fact if p is very close to a loop α_i, T_i will map p far away from its initial position. Since the intersection graph of α_js does not have any loops, it is not possible to compose this twist with other ones and take p back near its initial position. It is implied then that p should be twisted only slightly by each of the T_is. Now if p is away from the critical points of h, it will be twisted only by one of the maps T_i. This twist will either increase or decrease the value of h since α_i is a gradient flow line. So p can not be a fixed point unless it is around one of the critical points of h.

We should then analyze what happens near critical points of h. Because of the assumption on h the following cases are the only possibilities:

1) p is around an index-1 critical point q of h where $\{q\} = \alpha_i \cap \alpha_j$. The two loops are locally the stable and unstable manifolds of q. The local picture is shown in figure 2(a). One gets 4 regions labeled $1, 2, 3, 4$. For the fixed point p of T^ϵ, the twists and the flow do not change the region of p if ϵ is chosen to be small enough. Let $y(p)$ denote the y-coordinate of the point p in the xy-plane shown in figure 2(a). By analyzing the local behavior of H^ϵ and T, one may find out that in the regions 1,3, for any point p, $y(T(p)) > y(p)$ and $y(H^\epsilon(p)) > y(p)$. Similarly in the regions 2,4, $y(H^\epsilon(p)), y(T(p)) < y(p)$. So T^ϵ may not have a fixed point near such an intersection point q.

2) The next possible case is a local minimum for $h|_{\alpha_i}$ at some index one critical point. The only difference from figure 2(a) is that there is no α_j in the picture. The argument is identical to the above, since T, H^ϵ still increase the y-coordinate in the regions 1,3 and decrease it in 2,4.

3) An index-2 critical point of h on a curve α_i; The local picture is shown in figure 2(a). Here there are two regions and the x-coordinate is increased by T, H^ϵ in one of them and is decreased in the other one. Again there can not be any fixed points. □

If h is our Morse function, $h^{-1}(3)$ will be a submanifold, hence a collection of circles on Σ. One may assume that near these circles the manifold is a product $[2,4] \times S^1$, h is the projection on the first factor, and that ω and the almost complex structure are standard on $[2,4] \times S^1$. Following an argument similar to that of Gautschi's ([4]) we choose a subset $I_0 = [3-\delta, 3+\delta] \subset [2,4] = I$ and consider a bump function λ_R which takes the value R on I_0 and is equal to 1 near the ends of I. Then we may think of λ_R as a function on Σ which is equal to the constant function 1 outside the above product neighborhoods and on these neighborhoods is given by the value of the above function on the first factor.

Multiply the symplectic form by λ_R, but keep the almost complex structure fixed. Call the new symplectic form ω_R. It is clear that the moduli space of holomorphic curves does not change. We will use ω_R for large R to reduce the boundary computations to the case of Hamiltonian isotopy.

3. ENERGY BOUNDS

Before going through the next few technical steps, let us see how they are related to the bounds on the energy of pseudo-holomorphic disks connecting the fixed points. Fix a symplectic form ω on Σ such that T becomes a symplectomorphism and ω is standard in the parts described in the last

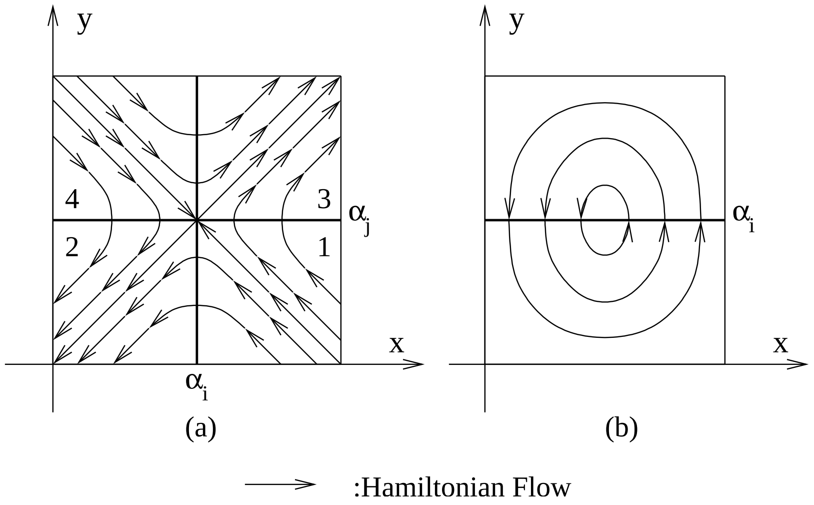

FIGURE 2. Local behavior; (a) The intersection at index-1 critical points of h of α_i, α_j (b) α_i passes through an index-2 critical point of h

paragraph of section 2.

Keeping the notation of section 2, for $x_-, x_+ \in$Fix(T^ϵ) let $\pi_2(x_-, x_+)$ be the space of isotopy classes of maps $\varphi : \mathbb{R} \times \mathbb{R} \to \Sigma^R$ s.t.

$$\varphi(s,t) = T^\epsilon(\varphi(s,t+1)) \quad \forall s,t \tag{2}$$

$$\lim_{s \to \pm\infty} \varphi(s,t) = x_\pm .$$

For $\varphi \in \pi_2(x_-, x_+)$ define $\mathcal{M}(\varphi)$ to be the space of maps $u : \mathbb{R} \times \mathbb{R} \to \Sigma$ representing $[\varphi]$ s.t.

$$\frac{du}{ds} + J(u(s,t))\frac{du}{dt} = 0 \quad \forall s,t. \tag{3}$$

Denote the expected dimension of this space by $\mu(\varphi)$. $\mathcal{M}(\varphi)$ is obviously equipped with an $\mathbb{R}$-action which is the translation in the second factor. We consider the Floer complex generated by $\{p\}_{p \in \mathrm{Fix}(T^\epsilon)}$. The boundary maps are defined by:

$$\partial(p) := \sum_{\substack{q \in \mathrm{Fix}(T^\epsilon) \\ \varphi \in \pi_2(p,q) \\ \mu(\varphi)=1}} \#(\mathcal{M}(\varphi)/\mathbb{R}) \cdot q \ . \tag{4}$$

If the almost complex structure J and the perturbation are generic enough then this will define a homology group denoted by $HF^*(T)$.

Proposition 3.1. *Suppose that* $\Sigma \setminus \cup_{i=1}^{n}\alpha_i = \cup_{j=1}^{m} V_j$*, where* V_j*s are the connected components. If* $x_-, x_+ \in Fix(T^\epsilon)$ *are not in the same* V_j*, then* $\pi_2(x_-, x_+)$ *will be empty.*

As a result we may restrict ourselves to the fixed points on the same piece. The next result is:

Proposition 3.2. *For* $x_-, x_+ \in Fix(T^\epsilon)$ *in the same piece* V_j *and* $\varphi \in \pi_2(x_-, x_+)$ *,* $u \in \mathcal{M}(\varphi)$*, the energy of* u *is* $E(u) = n(\varphi)(\int_\Sigma \omega_R) + \epsilon(h(x_+) - h(x_-))$*, for some integer* $n(\varphi) \geq 0$ *that only depends on the homotopy class* φ*.*

Note that the energy depends on the metric and if the metric is defined using the almost complex structure J and the symplectic form ω_R, then ω_R will naturally enter to any formula for the energy.

This energy bound will be used later to rule out some potential holomorphic orbits.
In the rest of this section we will focus on the proof of the above two statements.
Put $T_\pi := T_{\pi(n)} \circ T_{\pi(n-1)} \circ ... \circ T_{\pi(1)}$, for any element $\pi \in S_n$ (the symmetric group in n letters). Here T_i is the positive Dehn twist along α_i. The map in question will be $T = T_{Id}$. We claim the following:

Lemma 3.3. *Associated with any* $\pi \in S_n$*, is a diffeomorphism* $f : \Sigma \to \Sigma$ *such that* $T_\pi = f \circ T_{Id} \circ f^{-1}$*. Moreover,* f *may be chosen to be a combination of the twists* T_i *and their inverses.*

Proof. To prove the lemma, we use the following simple combinatorial fact:

Lemma 3.4. *Let* G *be a* forest*, with vertices labeled* $1, 2, ..., n$*. Put these numbers around a circle (with some arbitrary order) . At each step one may interchange* i, j *on the circle, if they are not adjacent in* G*, but are neighbors on the circle. Using these moves, it is then possible to get any permutation* $\pi(1), \pi(2), ..., \pi(n)$ *of* $1, 2, ..., n$ *around the circle in finitely many steps.*

□

If G is the associated graph of the loops $\alpha_i, i = 1, ..., n$ and i, j are not adjacent in G, then $T_i \circ T_j = T_j \circ T_i$. So for $\pi \in S_n$ with $\pi(l) = i, \pi(l+1) = j$,

$T_\pi = T_\sigma$ where $(i,j)\circ\pi = \sigma$. Also, if $\pi(1) = i, \pi(n) = j$ with i, j not adjacent in G then for $\sigma = (1,n)\circ\pi$ we find $T_\sigma = T_{\pi(1)} \circ T^{-1}_{\pi(n)} \circ T_\pi \circ T^{-1}_{\pi(1)} \circ T_{\pi(n)} = f_{\pi(1),\pi(n)} \circ T_\pi \circ f^{-1}_{\pi(1),\pi(n)}$ where $f_{i,j} = T_i \circ T_j^{-1}$. In order to get to T_π from T_{Id}, one may then follow the steps determined by lemma 3.4. □

Lemma 3.5. *Let T, α_i be as above. If β is a path on Σ such that T fixes the ends of β and $T\beta$ is homologous to β, then β has zero intersection number with all $[\alpha_i]$s.*

Here by "$T\beta$ is homologous to β" we mean that $T\beta - \beta$ is homologous to zero as a closed 1-chain.

Proof. We will prove the lemma in the case where the intersection graph

G is a tree (i.e. connected). The general case may be proved with a small variation.
Using lemma 3.3, for each π there is some $f : \Sigma \to \Sigma$, which is a composition of twists, such that $T = f^{-1} \circ T_\pi \circ f$. If the lemma is true for T_π, and β is as above, then $T\beta = (f^{-1} \circ T_\pi \circ f)\beta$. From the assumption, one verifies that $T_\pi[\theta] = [\theta]$ for $\theta = f\beta$. Then the lemma applied to T_π implies that $f[\beta]$ has intersection number zero with all $[\alpha_i]$s. Since f is a combination of twists along α_is, it follows that the lemma is also true for T . In other words, it is enough to verify the lemma for a specific choice of the order of the twists.

To choose the appropriate order, note that the loops corresponding to the vertices which are not leaves of G form an independent subset of $H_1(\Sigma, \mathbb{Q})$ as a vector space over $\mathbb{Q}$. Extend this subset to a basis of the subspace generated by all α_is in $H_1(\Sigma, \mathbb{R})$ by inserting some of the loops corresponding to the leaves of G. Denote the elements of this basis by $\beta_1, ..., \beta_k$ and the rest of α_is by $\gamma_1, ..., \gamma_l$. Let $\eta_1, ..., \eta_r$ be the set of curves among β_js which are associated with vertices of G that are neighbors of the leaves of G. The remaining vertices (those that are not among γ_is and η_js) may be divided into three groups A, B, C as follows: C is the group of leaves of G among $\{\beta_1, ..., \beta_k\}$. The remaining vertices are divided into two sets A, B such that no element of A is adjacent to an element of B. We will first do the twists along elements of A, then along elements of B and then elements of C. Afterwards the twists along η_js , which we will call the group D, are done, and finally we do the twists along the elements of group E which are γ_is. Let $\delta_1, ..., \delta_n$ be the same as $\beta_1, ..., \beta_k, \gamma_1, ..., \gamma_l$ but with the new ordering and accordingly, suppose that $\Gamma = [\gamma_1, ..., \gamma_l] = [\delta_1, ..., \delta_k]A^T = \Delta A^T$.

First, suppose that β is a closed loop. If $\lambda_i = (\beta|\delta_i), \theta_j = (\beta|\gamma_j)$, then $\Theta = A\Lambda$, and one should show that $\Lambda = 0$, where the ith entry of Λ is λ_i and the jth entry of Θ is θ_j.

Consider the matrix $\Upsilon=[\epsilon_{ij}]$ with $\epsilon_{ij}=1$ if δ_i,δ_j meet in a point and $i<j$ (otherwise, ϵ_{ij} is defined to be zero). Since we are considering positive Dehn twists, in the level of homology, S_i (the twist along δ_i) is given by: $S_i[\delta]=[\delta]+(\delta|\delta_i).[\delta_i]$.
It is then easy to check that:

$$[\beta]=S[\beta]=[\beta]+\begin{pmatrix}\Lambda^T & \Theta^T\end{pmatrix}(I+\Upsilon+\Upsilon^2+...)\begin{pmatrix}\delta_1\\ \vdots\\ \delta_n\end{pmatrix}. \tag{5}$$

Replacing $\Theta=A\Lambda$, it is enough to show that $B=\begin{pmatrix}I & A^T\end{pmatrix}(I-\Upsilon)^{-1}\begin{pmatrix}I\\ A\end{pmatrix}$ is invertible to get $\Lambda,\Theta=0$ (since $[\delta_1],...,[\delta_k]$ are independent). The matrix $(I-\Upsilon)$ has the form: $\begin{pmatrix}I-E & -X\\ O & I\end{pmatrix}$ where x_{ij} is 1 iff δ_i is the unique vertex among η_ps that is adjacent to γ_i, and is zero otherwise. So

$$(I-\Upsilon)^{-1}=\begin{pmatrix}(I-E)^{-1} & Y\\ 0 & I\end{pmatrix}, \tag{6}$$

with $X=(I-E)Y$. Hence $B=(A^T+Y)A+(I-E)^{-1}$ which is invertible iff its multiplication on the left by $(I-E)$ is.

Decompose all of the matrices into the block corresponding to the groups A,B,C,D. Then:

$$\begin{aligned}\Delta&=[\Delta_A\quad \Delta_B\quad \Delta_C\quad \Delta_D]=[\delta_1,...,\delta_k]\\ A&=[A_A\quad A_B\quad A_C\quad 0]\\ X^T&=[0\quad 0\quad 0\quad X_D^T]\end{aligned} \tag{7}$$

$$E=\begin{bmatrix}0 & \Delta_A^T.\Delta_B & 0 & \Delta_A^T.\Delta_D\\ 0 & 0 & 0 & \Delta_B^T.\Delta_D\\ 0 & 0 & 0 & \Delta_C^T.\Delta_D\\ 0 & 0 & 0 & \Delta_D^T.\Delta_D\end{bmatrix}.$$

Notice that $(\Delta_A^T.\Delta_B)A_B$ is zero since:

$$0=\Delta_A^T.\Gamma=(\Delta_A^T.\Delta)A^T=(\Delta_A^T.\Delta_B)A_B, \tag{8}$$

where the last equality follows from the fact that $\Delta_A^T.\Delta_A,\Delta_A^T.\Delta_C,A_D$ are all zero. Consequently:

$$EA^T=[(\Delta_A^T.\Delta_B)A_B\quad 0\quad 0\quad 0]^T=0. \tag{9}$$

This means that $(I-E)B=I+A^TA+XA$ which is always invertible for any A,X of the above block form.

Now suppose that β is not closed. Then we will have:

$$\Theta = \beta.\Gamma^T = A(\beta.\Delta^T) + R^T = A\Lambda + R^T, \tag{10}$$

which means that we will get:

$$\begin{aligned} S[\beta] = [\beta] + \Lambda^T \begin{pmatrix} I & A^T \end{pmatrix} (I-\Upsilon)^{-1} \begin{pmatrix} I \\ A \end{pmatrix} \begin{pmatrix} \delta_1 \\ \vdots \\ \delta_k \end{pmatrix} \\ + R \begin{pmatrix} \gamma_1 \\ \vdots \\ \gamma_l \end{pmatrix}. \end{aligned} \tag{11}$$

Putting $Q = \Lambda^T(I-E)^{-1}$, this equation reads as:

$$0 = Q(I + A^T A + XA)\Delta^T + R\Gamma^T. \tag{12}$$

Put $Q = \Lambda^T(I-E)^{-1}$. Then $Q(I + A^T A + XA) + RA = 0$. If $Q = [Q_A, Q_B, Q_C, Q_D] = [Q_0, Q_D]$ and similarly $A = [A_0, 0], X^T = [0, X_D^T]$ then this equation reads as:

$$[Q_0 \quad Q_D](I + \begin{bmatrix} A_0^T A_0 & 0 \\ X_D A_0 & 0 \end{bmatrix}) + [RA_0 \quad 0] = [* \quad Q_D] = 0. \tag{13}$$

So $Q_D = 0$ which implies that $QX = 0$. Combining this we the previous computation $(I-E)^{-1}A^T A = A^T A$ (which is the same as $EA^T A = 0$), it follows that:

$$\begin{aligned} 0 &= (\beta.\Delta)((I-E)^{-1} + A^T A) + RA \\ &= (\beta.\Delta)(I + A^T A(I-E)) + RA(I-E). \end{aligned} \tag{14}$$

Again using the block representation of the matrix E and the easy fact that $A_A \Delta_A^T \Delta_B = 0$, we see that:

$$\begin{aligned} AE &= [0 \quad A_A\Delta_A^T.\Delta_B \quad 0 \quad A\Delta^T.\Delta_D] \\ &= [0 \quad 0 \quad 0 \quad \Gamma^T.\Delta_D] = \Gamma^T.\Delta. \end{aligned} \tag{15}$$

The result is that

$$\begin{aligned} 0 &= (\beta.\Delta) + ((\beta.\Delta)A^T + R)(A - \Gamma^T.\Delta) \\ &= (\beta.\Delta) + (\beta.\Gamma^T)(A - \Gamma^T.\Delta). \end{aligned} \tag{16}$$

In particular by looking at the first three blocks we get:

$$0 = [\beta.\Delta_A \quad \beta.\Delta_B \quad \beta.\Delta_C] \begin{bmatrix} \Delta_A^T \\ \Delta_B^T \\ \Delta_C^T \end{bmatrix} + (\beta.\Gamma^T)\Gamma. \tag{17}$$

This means that $\sum_{\alpha\in\mathcal{A}}(\beta|\alpha)\alpha = 0$, where $\mathcal{A}$ is the set of all δ_is in A, B, C or E.

Let $\mathcal{B}$ be the set of elements $\alpha \in \mathcal{A}$ such that $(\beta|\alpha)$ is not zero. Then we claim that the elements of $\mathcal{B}$ are disjoint loops on Σ. The reason is that the associated graph of the elements of $\mathcal{B}$ is again a forest. If it has any edges then we may find elements $\eta, \mu \in \mathcal{B}$ such that they are connected in the associated graph and η is a leaf of this graph. Then:

$$0 = \sum_{\alpha \in \mathcal{B}} (\beta|\alpha)(\alpha|\eta) = (\beta|\mu)(\mu|\eta) = \pm(\beta|\mu), \tag{18}$$

which is a contradiction, since we had assumed that $(\beta|\alpha) \neq 0$ for all $\alpha \in \mathcal{B}$.

Lemma 3.6. *Suppose that β is a path on a surface Σ. If $\hat{\gamma_1}, ..., \hat{\gamma_r}$ are disjoint loops on Σ with $(\beta|\hat{\gamma_i}) \neq 0$ for all i and $\sum_i (\beta|\hat{\gamma_i})\hat{\gamma_i} = 0$ in the homology, then at least one of the $\hat{\gamma_i}$'s is homologically trivial.*

Proof. (of lemma 3.6) Suppose that $\partial D = \sum_i (\beta|\hat{\gamma_i})\hat{\gamma_i}$ and that $D = \sum_j n_j D_j$ with D_js domains on Σ and $n_i \neq n_j$ for $i \neq j$. Let $n_1 > ... > n_s$ and suppose that $n_1 > 0$ (changing β with $-\beta$ if necessary, this may be assumed). Since each boundary component is common between at most two of the domains and n_1 is the biggest of all n_js, $\partial D_1 = \sum_i a_i \hat{\gamma_i}$ (i.e. the boundary of D_1 is a combination of the loops) and a_i has the same sign as $(\beta|\hat{\gamma_i})$.
Since D_1 is a domain, $(\beta|\partial D_1) \leq 1$. On the other hand, $(\beta|\partial D_1) = \sum_i a_i(\beta|\hat{\gamma_i})$ and $a_i(\beta|\hat{\gamma_i}) > 0$ unless $a_i = 0$. Thus, exactly one of the a_is is nonzero and one of the loops should be homologically trivial. □

Since we have assumed that non of α_is is homologically trivial, it should be the case that $\mathcal{B}$ is empty, i.e. $(\beta|\alpha) = 0$ for any α in the groups A, B, C, E. In particular $\beta.\Gamma^T = 0$ which implies by equation 16 that $\beta.\Delta^T = 0$. This completes the proof of lemma 3.5. □

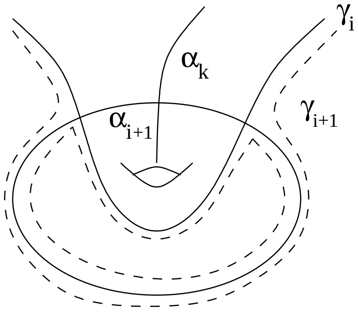

FIGURE 3. γ_{i+1} may be obtained from γ_i by connecting couples of intersection points with α_{i+1} along α_{i+1} and disjoint from α_k for $k \leq i$

Proof. (of proposition 3.1) Put $f = T^{\epsilon}$ and suppose that there exists a path γ from x_- to x_+ such that $[\gamma] - [f\gamma]$ represents the trivial homology class in the homology of Σ. By lemma 3.5, $[\gamma]$ has zero intersection number with all $[\alpha_i]$s.

Lemma 3.7. *Suppose that γ is a path from x_- to x_+ such that it has zero intersection number with all α_is. Then there is a union $\delta = \cup_j \delta_j$ of paths $\delta_j \subset$Fix(T) such that $[\delta] - [\gamma]$ represents the trivial homology class in Σ.*

Proof. After changing indices if necessary, we may assume that α_i intersects at most one α_k for $k < i$. Define γ_i as follows: $\gamma_0 = \gamma$. Suppose that γ_i is defined such that it does not cut $\alpha_1, ..., \alpha_i$ and it has zero intersection number with $\alpha_{i+1}, \alpha_{i+2}, ...$. One may divide the intersection points of α_{i+1} and γ_i into couples of positive and negative intersections, say $p^1_{\pm}, ..., p^k_{\pm}$. Cut γ_i at all $p^l_{\pm}$s to get several paths on Σ. Two of the end points of these paths are near p^l_+ and two are near p^l_-. Since $\alpha_{i+1} \setminus \cup^i_{j=1} \alpha_j$ is connected, we may connect these two pairs by two other paths parallel to $\alpha_{i+1} \setminus \cup^i_{j=1} \alpha_j$. If we do this for $l = 1, ..., k$ we will get a new 1-chain γ_{i+1} which does not cut $\alpha_1, ..., \alpha_{i+1}$ (see figure 3). $[\gamma_{i+1}] - [\gamma_i]$ is definitely homologically trivial, hence so is $[\gamma_{i+1}] - [\gamma]$. $\delta = \gamma_n$ will then be separated from all α_is and may be assumed to lie in Fix(T). □

Since x_-, x_+ will be the endpoints of one of the connected pieces of $\delta = \cup_j \delta_j$, it is automatically implied that they are on the same V_i. This finishes the proof of proposition 3.1 □

Proof. (of proposition 3.2) For an element $u \in \mathcal{M}(\varphi)$, the energy $E(u)$ is defined by:

$$E(u) = \int_{\mathbb{R}\times[0,1]} |du|^2 = \int_{\mathbb{R}\times[0,1]} u^*\omega_R, \tag{19}$$

where $\varphi \in \pi_2(x_-, x_+)$ and the metric is given using ω_R and J.
If x_-, x_+ are in the same piece and $\gamma(s) = u(s, 1)$ then $T\gamma$ is homologous to γ, which implies by proposition 3.1 and lemma 3.7 that there is a 1-chain δ in $Fix(T)$ homologous to γ. Define $v_j(s,t) = (H^{(1-t)\epsilon}(\delta_j(s)), t)$ where δ_js are different pieces of δ. If L is the 2-chain with $\partial[L] = [\gamma] - [\delta]$, and $\tilde{u}(s,t) = (u(s,t), t)$ then

$$[K] = [L \times \{1\}] - (\sum_j [v_j]) + [\tilde{u}] - [f(L) \times \{0\}]$$

defines a homology class in $H_2(\Sigma \times \mathbb{R}) = H_2(\Sigma)$. So

$$[K] = n(\varphi)[\Sigma]. \tag{20}$$

Note that $n(\varphi)$ does not depend on the representative u of φ. In fact if u_1, u_2 are representatives of the classes $\varphi_1, \varphi_2 \in \pi_2(x_-, x_+), u_i \in \mathcal{M}(\varphi_i)$ and $[K_1] = n_1[\Sigma], [K_2] = n_2[\Sigma]$ are the associated classes, then $n_1 - n_2 = [\{z\} \times [0,1]].([\tilde{u_1}] - [\tilde{u_2}]) = [\{z\} \times [0,1]].([\tilde{\varphi_1}] - [\tilde{\varphi_2}])$ and in particular if $\varphi_1 = \varphi_2$ then $n_1 = n_2$ (here, $\tilde{g}(s,t) = (g(s,t),t)$ for all g).

If we denote the pull back via the first projection $p_1 : \Sigma \times \mathbb{R} \to \Sigma$ of ω_R by ω_R as well, then:

$$\begin{aligned} \int_{[K]} \omega_R &= \int_{\mathbb{R}\times[0,1]} u^*\omega_R + \int_L \omega_R - \int_L f^*\omega_R - \sum_j \int_{\mathbb{R}\times[0,1]} {v_j}^*\omega_R \\ &= E(u) - \sum_j \int_{\mathbb{R}\times[0,1]} \omega_R(dv_j \frac{\partial}{\partial s}, \epsilon X_h(v_j)) \\ &= E(u) - \epsilon(h(x_+) - h(x_-)). \end{aligned} \tag{21}$$

Hence,

$$E(u) = n(\varphi)(\int_\Sigma \omega_R) + \epsilon(h(x_+) - h(x_-)), \tag{22}$$

which completes the proof of the proposition. □

4. Main Theorem

The content of this section is the proof of the following computation:

Theorem 4.1. *Let $(\Sigma, \alpha_1, ..., \alpha_n)$ be an acceptable setting and put $C = \cup_i \alpha_i$. Let ψ be the isotopy class of the combination T of the positive Dehn twists along α_is in some order in the mapping class group $\Gamma = \pi_0(Diff^+(\Sigma))$. Then $HF^*(\psi) = H^*(\Sigma, C)$ as $\mathbb{Z}/2$-graded $H^*(\Sigma)$-modules, where $H^*(\Sigma) = HF^*(Id)$ acts on the right hand side by the ordinary cup product and on the left hand side by quantum cup product.*

For a diffeomorphism $f : \Sigma \to \Sigma$, let $T_f\Sigma$ be the mapping torus of f defined by

$$T_f\Sigma := \frac{\Sigma \times I}{\sim} \quad (x,0) \sim (f(x),1) \quad \forall x \in \Sigma. \tag{23}$$

For $f \in Symp(\Sigma, \omega)$, the group of symplectomorphisms of Σ with respect to the symplectic form ω, let $\tilde{\omega}$ be the pull back of ω to $\Sigma \times \mathbb{R}$ and denote the induced form on $T_f(\Sigma)$ by $\tilde{\omega}$ as well. $T_f(\Sigma)$ is fibered over S^1. The Euler class of the tangent plane bundle along the fibers of $T_f(\Sigma)$, will be an element c_f of $H^2(T_f(\Sigma), \mathbb{R})$. Consider the exact sequence:

$$... \to H^1(\Sigma, \mathbb{R}) \xrightarrow{Id - f^*} H^1(\Sigma, \mathbb{R}) \xrightarrow{d} H^2(T_f(\Sigma), \mathbb{R}) \to H^2(\Sigma, \mathbb{R}) \to 0. \tag{24}$$

Since $[\tilde{w}] - \frac{\int_\Sigma \omega}{\chi(\Sigma)}[c_f]$ vanishes when restricted to the fibers, it will be of the form $d(m(f))$ with $m(f) \in H^1(\Sigma, \mathbb{R})/Im(Id - f^*)$. $m(\varphi)$ is called the *monotonicity class* and f is called *monotone* if $m(f) = 0$ or saying it differently, if $[\tilde{\omega}] = \frac{\int_\Sigma \omega}{\chi(\Sigma)}[c_f]$. It is proved in [10] that if two monotone symplectomorphisms represent the same isotopy class $[\psi]$ in the mapping class group Γ then they will give the same Floer cohomology denoted by $HF^*([\psi])$. It is also shown that there are monotone representatives in each isotopy class.

Lemma 4.2. *T^ϵ is monotone.*

Proof. Put $f = T^\epsilon$. We should show that for a class $[\gamma] \in H_1(\Sigma, \mathbb{R})$ with $[f_*(\gamma)] = [\gamma]$, $\eta = \tilde{\omega} - \frac{\int_\Sigma \omega}{\chi(\Sigma)}[c_f]$ evaluates zero on the homology class associated to $[\gamma]$ in $H_2(T_f(\Sigma), \mathbb{R})$.
If for some two chain L_0, $\partial[L_0] = [\gamma] - [f(\gamma)]$ then the class in $H_2(T_f(\Sigma))$ associated to $[\gamma]$ is the image of $[L_1] = [\gamma \times [0,1]] - [L_0 \times \{0\}]$ under the quotient map $\pi : \Sigma \times [0,1] \to T_f(\Sigma)$.

By lemma 3.5 γ has zero intersection with α_is and by lemma 3.7 (applied to $x_- = x_+$ on γ) it is homologous to a sum $\sum_j \delta_j$ of loops fixed by T^R. Let $\partial[L_2] = [\gamma] - \sum_j [\delta_j]$ and define v_js as in the proof of proposition 3.2. Then:

$$[K] = [L_2 \times \{1\}] - (\sum_j [v_j]) + L_1 - [f(L_2) \times \{0\}] \tag{25}$$

will be a homology class in $H_2(\Sigma \times \mathbb{R}) = H_2(\Sigma)$. The pull back of η evaluates to zero on this class. Since ω_R is invariant under f, and c_f comes from the cohomology of $T_f(\Sigma)$, the evaluation of η on $[L_2 \times \{1\}] - [f(L_2) \times \{0\}]$ will be zero as well. One can choose a trivialization of the 2-plane bundle in a neighborhood of δ_j and pull this trivialization back via $H^{(t-1)\epsilon}$ to $v_j(.,t)$ to get a trivialization along $[v_j]$. So c_f is trivial on $[v_j]$s. Finally the same argument as that of proposition 3.2 implies that the integration of $\tilde{\omega}^R$ on the 2-chain $[v_j]$ is zero.
Consequently η is zero on $[L_1] \in H_2(T_f(\Sigma), \mathbb{R})$. □

Proof. (of theorem 4.1) $\pi_2(\Sigma)$ is trivial, hence there is no bubbling off of holomorphic spheres. So the usual problem of non-compactness of moduli space is automatically solved in our case.

Since T^ϵ is a monotone representative of $[\psi]$ it can be used for the computation. By proposition 3.1 there are no disks between the fixed points in different pieces. Suppose that x_-, x_+ are two fixed points in the same piece V_j. We will show that all elements u of $\mathcal{M}(\varphi)$ (where $\varphi \in \pi_2(x_-, x_+)$,

$\mu(\varphi) = 1)$ satisfy $h(u(s,t)) < 3$ for all s, t.

If we connect x_-, x_+ by a path γ and put $\varphi_0(s,t) = H^{(1-t)\epsilon}(\gamma(s))$, then $E(\varphi_0) = \epsilon(h(x_+) - h(x_-))$ by proposition 3.2. On the other hand, from [10] we know that since $T^{\epsilon,R}$ is monotone, $\mu(\varphi) - \mu(\varphi_0) = \frac{\chi(\Sigma)}{\int_\Sigma \omega_R}(E(\varphi) - E(\varphi_0))$, since $T^{\epsilon,R}$ is monotone. Hence $\mu(\varphi) = \mu(\varphi_0) + n(\varphi)\chi(\Sigma)$. Since $\mu(\varphi_0)$ is the Morse-index difference of x_- and x_+ and $\chi(\Sigma) < 0$, the only possibilities for classes φ which contribute to equation (4) satisfy $n(\varphi) = 0$.

We claim that if $u \in \mathcal{M}(\varphi)$ for such φ, then the image of u should stay in $h^{-1}(-\infty, 3]$. Suppose that this is not true. Then we may find $s_0 < s_1, t_0 < t_1$ such that for $U = [s_0, s_1] \times [t_0, t_1] \subset \mathbb{R} \times [0,1]$ and any $(s,t) \in U$, $h(u(s,t)) \in I_0 = [3 - \delta, 3 + \delta]$. Then:

$$\begin{aligned} \epsilon(h(x_+) - h(x_-)) = \int_{\mathbb{R}\times[0,1]} |du|^2 &\geq \int_U |du|^2 \\ &= \int_U u^*\omega_R = R\int_U u^*\omega, \end{aligned} \tag{26}$$

which is a contradiction since we may assume that R is arbitrarily large. This proves the claim.

Put $S = h^{-1}(-\infty, 3]$ and note that the Hamiltonian flow maps S to itself. The Floer homology of this flow will give us the Floer homology of the map T by the above discussion. Then [8, theorem 7.3] shows that $\mathcal{M}(x_-, x_+)$ is homeomorphic to the space of $u : \mathbb{R} \to S$ such that

$$\frac{du}{dt} = -\nabla_J h(u) \quad \textit{with} \quad \lim_{t\to\pm\infty} u(t) = x_\pm. \tag{27}$$

for a generic choice of J, this gives the isomorphism we are looking for. ☐

Example 4.3.

On a surface of genus 2, suppose that the twists are done along the curves γ_i as shown in figure 4. Here the two pairs of shaded circles denote the attaching circles of the two 1-handles. If $T = T_{l+k+5} \circ T_{l+k+4} \circ ... \circ T_1$ where T_i is the positive twist along γ_i, then the matrix of the action of T on the first homology of Σ in the basis $\{[\alpha_1], [\beta_1], [\alpha_2], [\beta_2]\}$ will be:

$$\begin{pmatrix} 0 & 0 & -1 & 1 \\ -k & -k & kl & -1 \\ 1 & 0 & -l & 0 \\ 1 & 1 & -l & 0 \end{pmatrix}. \tag{28}$$

The characteristic polynomial will be $\chi_T(\zeta) = \zeta^2(\zeta+k)(\zeta+l) + (\zeta+k)(\zeta+l) + (1-kl)$. This polynomial is irreducible over $\mathbb{Z}$ if $k \equiv l \pmod 4$ and they are both odd (by "Eisenstein Criterion" applied to $\chi_T(\zeta+1), p = 2$). If $\chi_T(\zeta)$

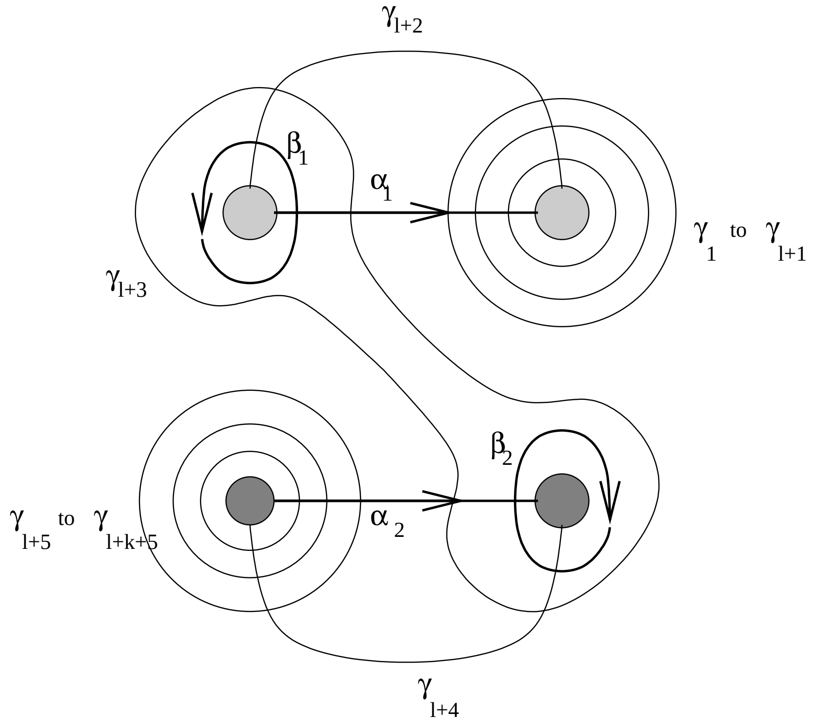

Figure 4. The map T is the combination of positive twists along γ_is

vanishes at some root of unity η, then it will be divisible by $\zeta - (\eta + \overline{\eta})\zeta + 1$ and $\eta + \overline{\eta}$ is a real number of absolute value at most 2. If $k, l > 4$, it can be easily seen that this is not the case. We quote the following two theorems from [1]:

Theorem A. *If for $f : \Sigma \to \Sigma$, the characteristic polynomial $\chi_f(\zeta)$ of the action of f on the first homology, is irreducible over $\mathbb{Z}$, has no roots of unity as zeros, and is not a polynomial in ζ^n for any $n > 1$, then f is irreducible and non-periodic.*

Theorem B. *Every non-periodic irreducible automorphism of a closed orientable hyperbolic surface is isotopic to a pseudo-Anosov automorphism.*

Accordingly, the map T will be representing a pseudo-Anosov class and theorem 4.1 explicitly computes the Floer homology associated to its class in the mapping class group.

Remark 4.4. *Note that lemma 3.5 remains true if T is a combination of positive twists along α_is and negative twists along α'_js where the associated* *graphs* G, G' *of* $\alpha_i s$ *and* $\alpha'_j s$ *are forests, no* α_i *meets an* α'_j *and none of the* $\alpha_i s$ *is homotopic to a* α'_j.

Definition 4.5. $(\Sigma, (\alpha_1, ..., \alpha_n), (\alpha'_1, ..., \alpha'_m))$ *is called a* strongly acceptable *setting if* $\alpha_i s$ *and* $\alpha'_j s$ *are as above and non of* $\alpha_i s$ *or* $\alpha'_j s$ *is homologically trivial.*

The procedure of proposition 2.1 may be applied "upside down" to give a Morse function h with $h(\alpha_i) \subset (4, \infty)$ and $h(\alpha'_j) \subset (-\infty, -4)$ with the similar properties. For T as above, T^ϵ may be defined as the composition of T with the Hamiltonian flow of h. Its fixed points will be the critical points p of h with $|h(p)| < 2$. Since the rest of our results do not remember the sign of the twists, one may prove the following theorem similar to theorem 4.1 (c.f. the result of [9]):

Theorem 4.6. *If* $(\Sigma, (\alpha_1, ..., \alpha_n), (\alpha'_1, ..., \alpha'_m))$ *is a strongly acceptable setting and* T *is the composition of positive Dehn twists along* $\alpha_i s$ *and negative twists along* $\alpha'_j s$*, in some order, then* $HF^*(T) \simeq H^*(\Sigma \setminus (\cup_i \alpha_i), (\cup_j \alpha'_j))$.

□

Remark 4.7. *Consider the quantum cup product*

$$* : H^*(\Sigma, \mathbb{Z}/2) \otimes HF^*(T) \quad \longrightarrow \quad HF^*(T).$$

The theorem just proven states that this map is the same as the usual cup product

$$\cup : H^*(\Sigma, \mathbb{Z}/2) \otimes H^*(\Sigma, C) \quad \longrightarrow \quad HF^*(\Sigma, C).$$

Clearly, $H^2(\Sigma, \mathbb{Z}/2)$ *acts trivially unless* C *is empty (i.e.* T *is the identity class) and for* $a \in H^1(\Sigma, \mathbb{Z}/2)$*, if the action on* $H^*(\Sigma, C)$ *is nonzero, then* a *is dual to a curve* $l : S^1 \to \Sigma$ *which does not cut* C*. This is to say that* $T(l) \simeq l$*. These are the special cases of [10, theorem 1,2] which are immediate because of the above computation.*
